Abstract: It is generally unknown how to formally determine whether different neural networks have a similar behaviour. This question intimately relates to the problem of finding a suitable similarity measure to identify bounds on the input-output response distances of neural networks, which has several interesting theoretical and computational implications. For example, it can allow one to speed up the learning processes by restricting the network parameter space, or to test the robustness of a network with respect to parameter variation. In this paper we develop a procedure that allows to compare neural structures among them. In particular, we consider dynamic networks composed of neural units characterised by non-linear differential equations, described in terms of autonomous continuous dynamic systems. The comparison is established by importing and adapting from the formal verification setting the concept of $\delta$-approximate bisimulations techniques for non-linear systems. We have positively tested the proposed approach over continuous time recurrent neural networks (CTRNNs).

Keywords: Continuous Time Recurrent Neural Network, Dynamic Networks, Bisimulation, Network Equivalence

1 Introduction

In recent years, a growing number of studies in computational neuroscience has focused on the question whether, in neural-network models having different parameters, similar input-output behaviours can be realized (see, for example, Prinz
et al., 2004; Marder and Goaillard, 2006; DiMattina and Zhang, 2010). This question naturally leads to the problem of defining a suitable similarity measure to functionally compare distinct neural networks.

The problem of specifying a computational procedure for a similarity measure which enables one to identify bounds on the input-output response distances of distinct neural networks has several interesting theoretical and computational implications. In the field of computational neuroscience, for example, such a procedure would allow one to quantitatively compare the network behaviours resulting from widely differing combinations of intrinsic and synaptic properties (MacGregor and Tajchman, 1988).

Interestingly, the above question is of great relevance in many engineering applications such as pattern recognition problems. For example, in supervised learning approaches (Bishop, 2006), different kinds of algorithms (e.g. gradient descent and evolutionary optimization techniques) are used to find the network-parameter values that minimize any functional error on the basis of some given training data set. Multiple minima give rise to multiple equivalent solutions to the same problem. Thus, the search for parameters by a supervised learning approach can often result in an ill-posed problem, insofar as one cannot uniquely identify a neural network from training the data only. A well-posed problem can be obtained in some special cases (e.g., standard MLP models): under special assumptions on the neuron output functions, the overall input-output relationship of the network uniquely determines the values of all network parameters, up to a permutation of neurons and the regrouping of identical neurons (Albertini and Sontag, 1993; Albertini et al., 1993; Wu et al., 2006). As a consequence, there are situations in which one may completely recover, in principle, the entire structure of a neural network just from the training data (Albertini and Sontag, 1993; Fefferman and Markel, 1994). However, the uniqueness of such results relies on the assumption that noiseless and potentially unlimited training data are available, thus restricting their applicability in the modelling of real data. A similarity measure may enable one to extend this class of well-posed problems insofar as one may determine classes of parameters which bring to “equivalent” or “sufficiently similar” neural networks. In this way, a functional mapping between training data and parameter classes would be possible, thereby turning the search for network parameters by a supervised approach into a well-posed problem.

In addition to this, a similarity measure would allow one to speed up the learning processes by restricting the parameter space during the learning phase (Neruda, 2000). Moreover, a similarity measure might be used to test and compare distinct neural networks (Horne and Giles, 1995) obtained by means of different learning algorithms. Consequently, this can let one choose between neural networks that look similar in terms of functionality by means of suitable heuristics over the complexity of the network architecture and specific requirements of the problem to solve.

The similarity question about neural-network models could be rephrased in the formal method framework (see Clarke et al., 2000). Such a framework provides powerful techniques to automatically and exhaustively check whether a system
satisfies a desired behaviour by checking whether a mathematical model of the system meets a mathematical representation of the desired behaviour. However, for complex systems such as non-linear dynamic networks, it is an open issue how to properly establish such a procedure (see Casagrande et al., 2012).

1.1 Our Contribution

In this paper we develop an effective procedure allowing one to compare different given neural structures when the parameters are varied. In particular, we consider dynamic networks composed of neural units characterised by non-linear differential equations and describable as autonomous continuous dynamical systems (Gupta et al., 2003; Munakata, 1997). We emphasize that dynamic networks are widely used in computational neuroscience as models of brain regions or subsets of biological neurons (Sporns, 2011; Chersi et al., 2013; Pezzulo et al., 2013; MacGregor, 2012; Izhikevich, 2007).

We collect a series of results in dynamical system theory and bisimulation theory in order to establish a dynamic network similarity (DyNeS) algorithm enabling one to functionally compare different dynamic networks. The comparison of networks is established by finding upper bounds between distance of trajectories, solutions of the equation of two neural networks. This is obtained by importing and adapting from formal verification framework $\delta$–approximate bisimulations techniques for non-linear systems (Girard and Pappas, 2005) to dynamic networks.

We stress that our approach introduces the bisimulation framework to non-linear dynamic networks, which results in the possibility of comparing the behaviour of different networks by means of the estimation of a bound $\delta$ between the systems in investigation. Without loss of generality, the present approach is tested within the continuous time recurrent neural network (CTRNN) framework, a popular network model widely deployed both in robotics (see e.g. Birch et al., 2002; De Falco et al., 2008; Paine and Tani, 2004; Montone et al., 2011) and computational models of biological neuronal phenomena (see e.g. Dunn et al., 2004; Donnarumma et al., 2010, 2012). Finally, note that the techniques used in this paper stem from very new research developments in dynamical system theory. This is the first attempt, to our best knowledge, to specialize bisimulation within the framework of non-linear dynamic networks.

1.2 Related Work

In the field of static neural networks a number of results about similarity between networks are present. It has been proved that the input-output functionality uniquely determines the network structure (Albertini and Sontag, 1993; Fefferman and Markel, 1994) in the case of infinite, noiseless data. Moreover, a biologically inspired method is presented in (DiMattina and Zhang, 2010), which allows to determine when the structure of a feed forward neural network can be gradually perturbed while preserving its functionality. This is accomplished by deriving a
differential equation that specifies the conditions under which the parameters of some given neural network can be continuously modified, while leaving the network functionality unchanged. Works by Amari and colleagues (Wei and Amari, 2008) characterised the behaviour of layered networks near singularities in order to help avoiding regions of parameters where standard gradient-based learning methods are stuck in large plateaus, greatly slowing training.

In the field of dynamic networks, a lot of efforts in literature have been devoted to establish conditions related to stability (see e.g. Cao et al., 2005; Yu and Yao, 2007; Chandrasekar et al., 2014): those approaches are linked to the method developed, in the sense that the similarity we adopted can be seen as a relaxation of the stability conditions. On the other side, in the formal method framework, different approximation techniques for extending formal methods to complex dynamical systems have been proposed (see e.g. Fränzle, 1999; Ratschan, 2010; Girard and Pappas, 2007a; Casagrande et al., 2009; Prabhakar et al., 2009; Lall et al., 2002). Those techniques are crucial in order to effectively study properties related to dynamical systems by means of computational procedures. Hybrid automata with noise are presented by Franzle in (Fränzle, 1999). The introduction of noise in many cases ensures the (semi-)decidability of the reachability problem. Another result of (semi-)decidability, again related to the concept of perturbation, is given by Ratschan in (Ratschan, 2010). Our approach is based on δ-(bi)simulation (Girard and Pappas, 2005) relations, which essentially corresponds to relaxations on the infinite precision required by simulation and bisimulation. Such relations represent a tool capable of removing complexity and undecidability issues related to the analysis of the investigated model. Following this last strategy, Lyapunov-like conditions can be developed in order to find bisimulation functions, which are used to over-approximate the observational distance between two polynomial systems, defining the so called δ—approximate bisimulations.

Unfortunately, dealing with the standard non-linear form of output function (e.g., the sigmoidal function), none of these techniques can be straightforwardly applied to dynamic networks. In this respect, however, it should be noted that a number of simplified dynamic network models are considered in literature. Studies reveal that approximation of output functions to cubic non-linearities still shows shapes, firing rates, and bursting behaviours throughout the physiological range (see Wilson, 1999). Second order polynomial approximations have also been considered in literature (see e.g. Rolls et al., 2006), but receiving less attention on how those models could be related to the non-approximated ones. Linearizing the non-linear components of the original continuous model, by replacing the sigmoidal outputs with sign functions (Ghosh and Tomlin, 2001; De Jong et al., 2004), lets continuous signals turn into discrete off-on signals. Unfortunately, it is proved that behaviours of those system models differ from the original one. A more sophisticated approximation of sigmoidals based on a piecewise linear function is exploited in the development of a hybrid automaton which simulates a single oscillator (Casagrande et al., 2012). We take a step further by considering “polynomialized” dynamic networks for which we show the possibility of computing useful δ—approximate bisimulations.
1.3 Work Plan

The rest of the paper is organized as follows. In Section 2, we propose the mathematical background of the dynamic network similarity (DyNeS) procedure. The pseudocode is presented in Subsection 2.3. The remaining subsections are devoted to the explanation of the steps of the procedure and include the details on the systems in use (Subsection 2.2), the polynomial approximation of the output function of the networks (Subsection 2.4) and the \( \delta \)-approximated bisimulation (Subsection 2.5). In Section 3, examples of the applications of the method are given, focusing on a particular model of dynamic networks, i.e. continuous time recurrent neural networks (CTRNN). Finally, in Section 4, conclusions and future work on the approach are envisaged.

2 Network Similarity Computation

2.1 Similarity Measure

In this section, we fully describe the computational steps in order to obtain the network similarity measure for dynamic networks. The pseudo-code of a dynamic network similarity (DyNeS) procedure is presented in Subsection 2.3. We start by clarifying the idea underlying our approach and the kind of systems on which it is performed. To exemplify the idea of similarity measure, we make use of the popular framework of multi-layered perceptron (MLP) network models (see Gardner and Dorling, 1998).

Given an MLP network \( G \), it is possible to write its input-output relation in terms of a functional relation \( y = f(x, \theta) \), where \( f \) is a parametric non-linear function, \( y = (y_1, \ldots, y_c) \) is the output of the neurons belonging to the output layer, \( x = (x_1, \ldots, x_d) \) is the input to the network, and \( \theta = (\theta^1, \ldots, \theta^n) \) is the parameter set encoding the network structure (e.g. synaptic weights and biases). Given two MLP networks \( G \) and \( \bar{G} \) with different structures \( \theta \) and \( \bar{\theta} \), a neural network similarity measure should enable one to find \( \delta \)-bounds on their responses, i.e., \( \forall x \in \mathbb{D} \subseteq \mathbb{R}^d \| f(x, \theta) - f(x, \bar{\theta}) \| < \delta \), the value of such \( \delta \) expressing a quantitative measure of how functionally close the networks \( G \) and \( \bar{G} \) are. Thus, the problem of comparing two networks can be reformulated as finding a suitable \( \delta \) that bounds so defined a distance between the two systems.

In the next section, we introduce the framework of continuous dynamic networks for which our approach has been developed. In contrast with MLP, continuous dynamic networks explicitly include the time in the model. Moreover, we stress that this kind of neural networks model are widely used in neuroscience literature and engineering applications.

2.2 Dynamic Networks Framework

We consider the framework of continuous dynamic networks in which the evolution of the system is expressed by means of first-order differential equations. Consequently, it is possible to study them as dynamical systems:
Definition 1. An autonomous continuous dynamic system $D$ is a 3-ple $(Q, \gamma, T)$ where

- $Q$ is a topological space named state space
- $T$ is the time set
- $\gamma : (y, t) \in Q \times T \rightarrow Q$ is the flow given by the solution of the set of first-order ordinary differential equations (ODE)

$$\frac{dy}{dt} = f(y)$$  \hspace{1cm} (1)

Thus, we refer to continuous dynamic networks when dealing with artificial neural network models satisfying Definition 1. In order to compare systems with a different number of variables, in Definition 2 the notion of a continuous dynamic network with observables is introduced.

Definition 2. An autonomous continuous dynamical system with observables $D = (Q, \gamma, T, h, H)$ is an autonomous continuous dynamical system $D = (Q, \gamma, T)$ additionally equipped with

- an observation space $H$, which is a metric space $H$ along with a metric $d$
- an observation map $h : Q \rightarrow H$, which maps variables of the state space $Q$ to the observation space $H$. The variables in the space $H$ are called observables.

Accordingly, one can define observable trajectories given by

$$\{(t, h(\gamma(y, t))) : \exists y \in Q, t \in T, \gamma(y, t) \in Q\}$$

From Definition 2, it is clear that a continuous dynamic network with observables is a continuous dynamic network where a mapping between the state space and an observation space is introduced. Thus, two dynamic networks with a different number of variables can be compared if one considers the same number of observable variables from each system and compares their observable trajectories. In particular, in order to show our approach we focus our attention on a popular model of dynamic networks.

Definition 3. Continuous time recurrent neural networks (CTRNNs) are networks of biologically inspired neurons (nodes) described by the following general equations (Hopfield and Tank, 1986; Beer, 1995):

$$\tau^i \frac{dy^i}{dt} = -y^i + \sum_{j=1}^{n} w^{ij} o(y^j + \theta^j) + I^i_c \quad i \in \{1, \ldots, n\}$$  \hspace{1cm} (2)

where $N$ is the number of neurons in the network and for each neuron $i$: $\tau^i$ is the time constant, $y^i$ is the potential or activation variable, $\theta^i$ is the bias, $o(y^i + \theta^i)$
is the mean firing rate, with $o(\cdot)$ the output function, $I^e_e = \sum_{j=n+1}^{n+l} w^{ij} u^j$ is an external input coming from $l$ external sources $u^j$, $w^{ij}$ is the weight of the connection coming from the node $j$.

From Equation (2), it is clear that CTRNN systems satisfy Definition 1 when networks parameters together with the external inputs $I^e_e$ are time independent. Usually $o(x)$ is the sigmoidal function $\sigma(x)$. However, one can choose as $o(x)$ any smooth, monotonic, and bounded activation function; the resulting network being called additive CTRNN. For example, one may use the parametric form (Tino et al., 2001)

$$o(x) = \sigma_{a,b,c}(x) = \frac{a}{1 + e^{-c x}} + b$$

(3)

that has the advantage of reducing to the hyperbolic tangent function by substituting $a = 2, b = -1, c = 2$ in (3) as follows

$$\sigma_{2,-1,2}(x) = \frac{2}{1 + e^{-2 x}} - 1 = \frac{e^x}{e^x} \cdot \frac{1 - e^{-2 x}}{1 + e^{-2 x}} = \frac{e^x - e^{-x}}{e^x + e^{-x}} = \tanh(x)$$

or one may use the standard sigmoid with $a = 1, b = 0, c = 1$, formally obtained from (3) as follows

$$o(x) = \sigma_{1,0,1}(x) = \frac{1}{1 + e^{-x}} = \sigma(x).$$

The sigmoidal output function $\sigma(x)$ is used throughout Section 3.

In the next subsection we will show how it is possible to find a clever approximation of the sigmoidal output function in order to apply the bisimulation techniques shown in Subsection 2.5. However, the approach presented here is quite general, insofar as similar results can be obtained for different activation functions fulfilling the smoothness, monotonic and boundedness conditions (see Section 4).

### 2.3 DyNeS Algorithm

It is possible to formalize in a pseudo-code fashion a similarity measure between dynamic network behaviours: in Algorithm 1 we present the main steps of the dynamic network similarity (DyNeS) procedure, which will be deeply clarified in the rest of this section.

The aim of the algorithm is to produce a $\delta_{max}$ between two dynamic networks, which bounds the trajectories of the two systems in time. This can be done by specifying a clever approximation of non-linear dynamic networks and then finding a bisimulation between the systems under investigation, which ensures that the trajectories have the property of being “sufficiently” close.

In Subsection 2.2 we described the kind of systems for which this procedure is applied (step 1). We will clarify the successive steps of Algorithm 1 in the rest of this section. Precisely, in Subsection 2.4 we show the approximation needed to
Algorithm 1 DyNeS Algorithm

Require: Given two continuous dynamic networks systems $D_1$ and $D_2$
1: select $k$ neurons from $D_1$ and $D_2$ respectively: this selection determines the comparing subspace on which the similarity will be computed;
2: select a proper polynomial approximation for networks output function on the basis of the dynamic networks connection weights $W$;
3: choose a suitable form of a parametric bisimulation function $V_c(y) : y \in \mathbb{R}^k \times \mathbb{R}^k \rightarrow V_c(y) \in \mathbb{R}^+$ with $y = \{y_1^1, \ldots, y_k^1, y_1^2, \ldots, y_k^2\}$ being the concatenation of the observable variables of $D_1$ and $D_2$ and $c = \{c_1, \ldots, c_L\}$ a suitable number $L$ of parameters. This bisimulation function enables one to establish a bisimilarity between $D_1$ and $D_2$, i.e., in a nutshell that the solutions of the two systems are “sufficiently close”;
4: compute by means of bisimulation function $V_c(y)$ an upper bound $\delta_{max}$ of the "distance" between the solutions of $D_1$ and $D_2$.

these systems in order to find the required bisimulation (step 2); in Subsection 2.5 we describe the bisimulation framework that lets us define a superior bound on measuring the similarity between the systems we compare (steps 3-4).

2.4 Polynomial Approximation of a network output function

In the presented framework of dynamic networks, it is possible to derive the following theorem:

Theorem 1. (Funahashi and Nakamura, 1993) Given a Dynamic Network $D$ in Definition 2 equipped with a sigmoidal output function, there exists $C$ such that

$$\|y(t)\| \leq \sqrt{n} \cdot C$$

with

- $C = \max\{C^n\}$,
- $C^n = \max\{y^n(0), M\}$,
- $M = n \cdot w_{max} + I_{max}$,
- $w_{max} = \max\{w_{ij}^n\}_{i,j=1}^n$,
- $I_{max} = \max\{I_{ie}^n\}_{i=1}^n$

Proof. We can write the equations as

$$\dot{y}^i = -\frac{y^i}{\tau^i} + \frac{F^i(y, W, I_e^i)}{\tau^i}$$

It is possible to find a constant $M$ such that $|F^i| \leq M$. In fact,
\[ F^n = \left| \sum_{j=1}^{n} w^{ij} \sigma(y^j + \theta^j) + I^i_e \right| \leq \sum_{j=1}^{n} \left| w^{ij} \right| \left| \sigma(y^j + \theta^j) \right| + \left| I^i_e \right| < \]

\[ \sum_{j=1}^{n} \left| w^{ij} \right| + \left| I^i_e \right| \leq n \cdot w_{max} + I_{max} = M \]

with \( w_{max} = \max \{ \left| w^{ij} \right| \}_{i,j=1}^{n} \) and \( I_{max} = \max \{ \left| I^i_e \right| \}_{i=1}^{n} \). Consequently, we can write:

\[ \left| y^i(t) \right| \leq \max \{ \left| y^i(0) \right| , M \} = C^i \]

from which the statement directly descends. \( \square \)

From Theorem 1 it directly derives that the argument of the sigmoidal function \( \sigma \) is bounded in a finite interval depending on the constants \([-A, A]\), where \( A = C + \theta_{max} \), with \( \theta_{max} = \max \{ \left| \theta^i \right| \}_{i=1}^{n} \). Thus, it is possible to use the following well known approximation result.

**Theorem 2.** [Weierstrass, 1885] For each continuous function \( f : x \in [a, b] \rightarrow \mathbb{R} \) defined on the closed and bounded interval \([a, b]\), then \( \forall \epsilon > 0 \) there exists some polynomial \( p(x) \) such that

\[ |p(x) - f(x)| < \epsilon \]

Consequently, for each dynamic network, it is possible to effectively construct an interval in which to perform a clever approximation, “as good as we want” of the initial system (see Subsection 3.1). Of course, the better an approximation is, the more polynomial terms are required, making the search for the bisimulation a more computationally difficult problem (see Subsection 2.5). Therefore, a trade-off strategy must be chosen, depending on the specific purpose for which the procedure is applied (see Section 4 for discussions).

### 2.5 \( \delta \)-approximate bisimulation for Dynamic Networks

The concept of bisimulation, as applied to state transition systems in verification of hardware and software systems (Clarke et al., 2000), can be used to establish topological equivalence between dynamical systems (Hale and Koçac, 1991). Here, we show how to relax bisimulation equivalence in order to perform a functional similarity measure between continuous dynamic networks.

In (Girard and Pappas, 2005) the concept of \( \delta \)-approximate bisimulation between transition systems (Clarke et al., 2000) was introduced. This approximate bisimulation, if established, identifies bounds on the distance between the trajectories of two distinct transition systems. \( \delta \)-approximate bisimulations between two transition systems can be achieved using classes of functions called bisimulation functions. In (Girard and Pappas, 2005) guidelines for identifying parametric bisimulation functions are proposed and shown to work in some case studies. As autonomous continuous dynamical systems can be considered as a subclass of the class of transition systems (Brihaye, 2006), one can specialize the \( \delta \)-approximate bisimulation method for the purpose of finding bisimulation functions in the Continuous Dynamic Network framework.
The classical notion of bisimulation reported in Definition 4 (see Clarke et al., 2000) can be formally seen as an equivalence relation, inducing a partition of the states of the involved transition systems (Zhang, 1994).

**Definition 4.** A relation $\sim$ is a **bisimulation** between two transition systems $G_1 \equiv (Q_1, \Sigma, \rightarrow_1)$ and $G_2 \equiv (Q_2, \Sigma, \rightarrow_2)$ such that $\forall (q_1, q_2) \in Q_1 \times Q_2$, $(q_1 \sim q_2)$ the following conditions are satisfied:

1. $\forall a \in \Sigma, \forall q'_1 \in Q_1 \mid q_1 \xrightarrow{a} q'_1 \implies \exists q'_2 \in Q_2 \mid q_2 \xrightarrow{a} q'_2$ and $(q'_1 \sim q'_2)$

2. $\forall a \in \Sigma, \forall q'_2 \in Q_2 \mid q_2 \xrightarrow{a} q'_2 \implies \exists q'_1 \in Q_1 \mid q_1 \xrightarrow{a} q'_1$ and $(q'_1 \sim q'_2)$

Bisimulation in Definition 4 guarantees that two structures have the same behaviours. In particular, exact bisimulations between two transition systems entail that their observations are (and remain) identical. Consequently, exact bisimulations are very difficult to establish for non-linear dynamical systems like dynamic networks, and like CTRNNs in particular.

The approximate bisimulation approach presented in Definition 5 (see Girard and Pappas, 2005) is less rigid, as it requires that the observations of approximately bisimilar systems are (and remain) arbitrarily close to each other.

**Definition 5.** A relation $\sim_\delta$ is a **$\delta$–approximate bisimulation** between two Continuous Dynamic Networks with observables $D_1 \equiv (Q_1, \gamma_1, T, h_1, H)$ and $D_2 \equiv (Q_2, \gamma_2, T, h_2, H)$ with a common time space $T$ and observation space $H$, such that $(\forall (y_1, y_2) \in Q_1 \times Q_2, (y_1 \sim_\delta y_2))$ the following conditions are satisfied:

1. $\forall t \in T, \forall y'_1 = \gamma_1(y_1, t) \in Q_1 \implies \exists y'_2 = \gamma_2(y_2, t) \in Q_2 \mid (y'_1 \sim_\delta y'_2)$

2. $\forall t \in T, \forall y'_2 = \gamma_2(y_2, t) \in Q_2 \implies \exists y'_1 = \gamma_1(y_1, t) \in Q_1 \mid (y'_1 \sim_\delta y'_2)$

**Note.** If $\delta = 0$, Definition 5 collapses into an exact bisimulation.

In other words, establishing a $\delta$–approximate bisimulation between two continuous dynamic networks guarantees that distances of the trajectories in the observation space are bounded by a value $\delta$ as stated by Theorem 3.

**Theorem 3.** (Girard and Pappas, 2007b) If there exists a $\delta$–approximate bisimulation between the two continuous dynamical networks $D_1$ and $D_2$, then for all observable trajectories of $D_1$ there exists a trajectory of $D_2$ such that $\forall t \in T$, $d(h_1(\gamma_1(y_1, t)), h_2(\gamma_2(y_2, t))) \leq \delta$ and viceversa.

The construction of approximate bisimulations between two transition systems, as well as the evaluation of their precision, can be performed using a class of functions called **bisimulation functions**, formally defined in Definition 6, which are positive functions defined on $Q_1 \times Q_2$, bounding the distance between the observations associated with a pair $(y_1, y_2)$ and non-increasing under the dynamics of the systems.
Definition 6. A bisimulation function $V$ is a continuous function

$$V : Q_1 \times Q_2 \rightarrow \mathbb{R}^+$$

with

1. $V(y_1, y_2) \geq d(h_1(y_1), h_2(y_2))$
2. $V(y_1, y_2) \geq \max_{y'_1 = \gamma_1(y_1, t)} \min_{y'_2 = \gamma_2(y_2, t)} V(y'_1, y'_2)$
3. $V(y_1, y_2) \geq \max_{y'_2 = \gamma_2(y_2, t)} \min_{y'_1 = \gamma_1(y_1, t)} V(y'_1, y'_2)$

Note that when restricting our study to the class of autonomous systems, Conditions 2 and 3 of Definition 6 become equivalent, and reduce to a Lyapunov-like condition. In particular, this can be considered as a weakening of Lyapunov stability conditions, in which one of the systems to compare collapses to the fixed-point solution. Similarly, the concept of bisimulation function is reminiscent of robust control Lyapunov functions (see Liberzon et al., 2002), though the latter require stronger conditions than bisimulation functions. Thanks to Theorem 4, the discovery of a bisimulation function is a sufficient condition to find a bisimulation relation between two systems.

Theorem 4. (Girard and Pappas, 2007b) If $V$ is a bisimulation function, then

$$\forall \delta \geq 0 \ the \ set$$

$$B_\delta = \{(y_1, y_2) \in Q_1 \times Q_2, V(y_1, y_2) \leq \delta\}$$

is a $\delta$-approximate bisimulation between dynamical networks $D_1$ and $D_2$.

In other words, Theorem 4 suggests the possibility of comparing observable trajectories of two continuous dynamic networks if one is able to describe a procedure to systematically compute suitable bisimulation functions for them.

Let us consider the case of two continuous dynamic networks $D_i$ with observables, where $i \in \{1, 2\}$, with equations $\dot{y}_i = f_i(y_i)$ where $y_i \in \mathbb{R}^{n_i}$, and with observation maps $h_i$, respectively. Let us further assume the hypotheses that $D_1$ and $D_2$ have the same observation space $\mathbb{R}^k$, equipped with the euclidean distance.

Now, by letting $y = [y_1; y_2]$ be an $(n_1 + n_2) \times 1$ column vector, $f(y) = \left[ f_1(y_1); f_2(y_2) \right]$ an $(n_1 + n_2) \times 1$ column vector, and $h(y) = h_1(y_1) - h_2(y_2)$ a $p \times 1$ column vector, one can state the following important theorem (see Girard and Pappas, 2005):

Theorem 5. Let $p : \mathbb{R}^{n_1} \times \mathbb{R}^{n_2} \rightarrow \mathbb{R}^+$ be a differentiable function with $\nabla p$ its gradient. If for all $y \in \mathbb{R}^{n_1+n_2}$ we have that $p(y)$ satisfies

$$p(y) \geq h(y)^T h(y)$$

(4)

$$\nabla p(y)^T f(y) \leq 0$$

(5)

then $V = \sqrt{p(y)}$ is a bisimulation function.
Thus, Theorem 5 ensures that finding a function $p(y)$ satisfying Conditions (4) and (5) lets us obtain a bisimulation function. Although this is a difficult task (Parrilo, 2003), there are techniques in semidefinite programming that allow one to find a sum of square form for $p(y) - h(y)h(y)$ and $-\nabla p(y)^Tf(y)$, resulting in a much simpler problem\footnote{It has been shown (see Parrilo, 2003) that the condition “$p(x)$ is a sum of squares” is computationally more tractable than $p(x) \geq 0$.}. However, note that this approach restricts the possible solutions, insofar as a sum of squares condition implies a positive condition, but the converse is not true. We, indeed, reduce the space of the functions, in which solutions are searched, to a subspace in which this search is more tractable.

Accordingly, it is possible to write a simpler formulation of Theorem 5, if one assumes that the vector fields $f_1(y)$ and $f_2(y)$ are expressed by polynomials.

**Theorem 6.** (Girard and Pappas, 2005) *Assuming the hypotheses that the autonomous vector fields $f_1$ and $f_2$ and the observation maps $h_1$ and $h_2$ are vectors of polynomials, then the conditions*

\[
p(y) - h(y)^Th(y) \text{ is a sum of squares}
\]

\[
-\nabla p(y)^Tf(y) \text{ is a sum of squares}
\]

*imply that $V(y) = \sqrt{p(y)}$ is a bisimulation function where $p(y)$ is a multivariate polynomial.*

With Theorem 6 the task of finding $p(y)$ satisfying Conditions (6) and (7) becomes manageable, and the bisimulation function can be computed in semidefinite programming\footnote{In particular, the algorithm subsumed by Theorem 6, SOSTOOLS Matlab toolbox (Prajna et al., 2002) will be deployed.}. Thus one can rewrite the steps 3-4 of Algorithm 1 in the light of this theorem:

3a* choose a sum of squares form $p^c(y)$

3b* find $c$ that minimizes $p^c(y)$ satisfying Theorem 6

4* find $\delta_{max} = \max_y \sqrt{p^c(y)}$

In the next section, we apply this DyNeS procedure to CTRNN equations, and show that this measure enables one to capture the error it is possible to tolerate in order to consider CTRNN systems as functionally bisimilar systems.

## 3 CTRNN comparison by DyNeS measure

In this section, we prepare and test systems whose functional equivalence is going to be evaluated by means of $\delta$–approximate bisimulation. First of all, we need a polynomial approximation of a CTRNN, due the fact that one cannot apply the bisimulation method explained in Subsection 2.5 directly to equations of...
CTRNNs whose flows are not polynomials. Following Subsection 2.4, this problem can be addressed by applying a machine learning procedure enabling one to approximate the CTRNN sigmoid function in a finite interval. In this way, in Subsection 3.1 we obtain a "polynomialized" version of the CTRNN system, which approximates the original one. Then, in Subsection 3.2 we prepared systems of one neuron networks, for which it is possible to theoretically characterize the space of the solutions when varying their parameters, in order to illustrate \( \delta \)-approximate bisimulation search. Finally, we test the procedure scalability on two and three neuron networks.

### 3.1 A polynomial approximation for CTRNN flows

The possibility of comparing two continuous dynamical networks by using approximate bisimulation was illustrated in Section 2.5. However, the application of Theorem 6 affords a comparison procedure only in the presence of polynomial flows of the system. Thus, the sigmoid output function prevents one from directly searching a bisimulation between CTRNN systems. On the other hand, a polynomial approximation of the sigmoidal function, "as good as we want" can be computed (see Subsection 2.4). More specifically, in this section we use regularized least square (see Bishop, 2006) in order to obtain a polynomial approximation for the sigmoid function

\[
\sigma(x) \approx \sum_{m=0}^{M} c_i \cdot x^m = \text{Pol}_M(x)
\]

which, in turn, enables one to obtain a polynomialized version of the CTRNN Equations (2):

\[
\tau_i \frac{dy^i}{dt} = -y^i + \sum_{j=1}^{N} w^{ij} \text{Pol}_M(y^j - \theta^j) + I^i_e \quad i \in \{1, \ldots, N\} \tag{8}
\]

This procedure, given a suitable polynomial order \( M \), allows one to approximate, to any desired precision, the behaviour of the sigmoid function in some given interval. In order to apply the regression algorithm, input-output pairs of the sigmoid function \( \sigma(x) \) in a fixed interval \([x_{\min}, x_{\max}]\) are prepared. The coefficients found for a \( \text{Pol}_M \) are searched in an interval \([-30, 30]\). Fig. 1 shows the behaviour of this approximation for \( M = 1, M = 3, M = 8 \) compared to the sigmoid function \( \sigma(x) \). Table 1 shows that the mean errors \( \bar{E} \) corresponding to different \( \text{Pol}_M \) decreases with the order of the polynomial. In the application of the bisimilarity procedure we choose \( M = 8 \) and the corresponding \( \text{Pol}_8(x) \). The two systems are comparable as long as each neuron activation value \( y_i \) of the CTRNNs is in \([x_{\min}, x_{\max}]\). However, if the solution of the systems lets the activations range on values outside this interval, then it is possible to regress a new \( \text{Pol}_M(x) \) which approximates \( \sigma(x) \) in a wider range.

3.2 Methods explained for simple CTRNNs

In this section we built different examples in order to show how to compare two CTRNNs by means of the DyNeS measure. In the first set of tests, we consider simple systems made up of a single neuron:

\[ \dot{y} = -y + w \cdot \sigma (y + \theta) + I \]  

(9)

where for simplicity we set the time constant \( \tau = 1 \). Notice that no elementary expression for the solution of (9) exists. By contrast, it is possible to achieve a complete qualitative description of its dynamics (Beer, 1995). Specifically, one can describe the limit sets of (9), including their stability and their dependence on the parameters, as well as the bifurcations that can occur as the parameters are varied (see Fig. 2). Such system has a cusp point (Hale and Koçac, 1991). This cusp point \((\tilde{w}, \tilde{I})\) is the only bifurcation point in which the system undergoes a pitchfork bifurcation (Hale and Koçac, 1991). All other bifurcation points are saddle-node bifurcations.

Thus, let us consider the two one-neuron systems \( \tilde{D}_1 \) and \( \tilde{D}_2 \)

\[ \tilde{D}_1 \equiv \begin{\{ \begin{array}{l} \dot{y}_1 = -y_1 + w_1 \cdot \sigma(y_1) + I \\ h_1 = y_1 \end{array} \end{\} } \]

and

\[ \tilde{D}_2 \equiv \begin{\{ \begin{array}{l} \dot{y}_2 = -y_1 + w_2 \cdot \sigma(y_2) + I \\ h_2 = y_2 \end{array} \end{\} } \]

In order to apply Theorem 6 the flows of the system have to be vectors of polynomials. Thus, we “polynomialize” the CTRNN equations as shown in the previous section, obtaining the new systems

\[ D_1 \equiv \begin{\{ \begin{array}{l} \dot{y}_1 = -y_1 + w_1 \cdot Pol_M(y_1) + I \\ h_1 = y_1 \end{array} \end{\} } \]

and

\[ D_2 \equiv \begin{\{ \begin{array}{l} \dot{y}_2 = -y_1 + w_2 \cdot Pol_M(y_2) + I \\ h_2 = y_2 \end{array} \end{\} } \]

We choose the identity functions as the observation maps: this means that we are going to directly compare activations \( y_1 \) and \( y_2 \) of the two systems. In this case the term \( h(y)^2 h(y) \) in Condition 6 turns into \((y_1 - y_2)^2\). This suggests that the polynomial form of the bisimulation function must be at least of the second order. We choose quite a general form, including terms up to the second order:

\[ V(y_1, y_2; \{c_i\}_{i=0}^5) = \sqrt{p(y_1, y_2)} = \sqrt{c_0 + c_1 \cdot y_1 + c_2 \cdot y_2 + c_3 y_1 \cdot y_2 + c_4 \cdot (y_1)^2 + c_5 \cdot (y_2)^2} \]

Let us firstly consider the case in which there is a global stable equilibrium point in the equation, so that, for any of the initial conditions of the variables \( y_1 \) and \( y_2 \), the asymptotic solution is unique. Consequently, we set \( I = 0 \) for both \( D_1 \) and \( D_2 \), the weight \( w_1 = -15 \) for system \( D_1 \), and for \( D_2 \) we choose
Figure 2: The two branches of the cusp of Equation 9 (where $\theta$ is set to 0), in the parameter space $(w, I)$. Outside two cusp branches, the system has a global stable equilibrium point. Inside the branches there are three equilibria: an unstable one and two stable ones.
Table 2: The parameters of the bisimulation function $V(y_1, y_2, \{c_i\}_{i=0}^5$ between $D_1$ and five versions of system $D_2$ with $w_2 \in \{-16, -17, -18, -19, -20\}$. We consider the case in which the initial conditions of the observable variables are identical ($y_1^0 = y_2^0$) and are in the closed and bounded interval $[-1, 1]$.

$w_2$ belonging to the set $\{-16, -17, -18, -19, -20\}$, thus obtaining five different versions of $D_2$, one for each $w_2$ value. We compare the $D_1$ system so obtained with the five different versions of system $D_2$. Thus minimizing the condition of $V(y_1, y_2, \{c_i\}_{i=0}^5$ under which the initial conditions of the observable variables are identical ($y_1^0 = y_2^0$), and in the closed interval $[-1, 1]$, we obtain the parameters $c_i$ of the bisimulation function for each system $D_2$. Table 2 shows the values of the identified parameters, while in Table 3 the corresponding values of the similarity measure are shown. Note that, as we expected, increasing values of $\delta_{\text{max}}$ are found, as long as system $D_2$ behaves “more differently” with respect to $D_1$.

In Fig. 3 numerical simulations of the original system $D_1$ versus the different versions of system $D_2$ are shown. As it was expected, the errors on trajectories shown are completely consistent with the $\delta_{\text{max}}$ error in Table 3. In fact, Subfigure 3a shows sample trajectories solutions of the compared systems, Subfigure 3b shows that solutions of $D_2$ depicted with their $\delta_{\text{max}}$-area include solutions of $D_1$. Furthermore, we simulated 500 different solutions for each $D_2$ system, with different initial conditions fulfilling ($y_1^0 = y_2^0$). Thus, at each time we computed an experimental $\delta_{\text{exp}}(t) = \max \left\{ \| y_1(t) - y_2^{(i)}(t) \| \right\}_{k=1}^{500}$. In Subfigure 3c the ratio $(\delta_{\text{max}} - \delta_{\text{exp}}(t))/\delta_{\text{max}}$ is plotted, resulting in values greater than zero, meaning that the $\delta_{\text{max}}$ bound is never crossed.

A second test is made on the same $D_2$ system, but now searching for an initial condition of the observable variables $y_1^0 \neq y_2^0$ in the same interval $[-1, 1]$. In this case the minimization is run in order to find parameters that a posteriori minimize the bisimulation function $V(y_1, y_2, \{c_i\}_{i=1}^5)$ on any possible initial conditions in $[-1, 1]$. The parameters for the bisimulation function are shown in Table 4. In
Figure 3: In Panel (a) some numerical simulations of system $\tilde{D}_1$ versus different versions of the system $\tilde{D}_2$ are shown. $\tilde{D}_1$ and $\tilde{D}_2$ are one-neuron CTRNNs. In Panel (b), each solution of $\tilde{D}_2$ is depicted as a $\delta_{\text{max}}$-coloured area with values in Table 3. As an example the area of $\tilde{D}_2$ with $w_2 = -20$ includes all areas with $w_2 > -20$. All the areas of $\tilde{D}_2$ include the solution of $\tilde{D}_1$. That means that the shown distance between trajectories of $\tilde{D}_1$ and $\tilde{D}_2$ are completely contained, as it was expected, in the $\delta_{\text{max}}$ error. In Panel (c), the ratio $(\delta_{\text{max}} - \delta_{\text{exp}})/\delta_{\text{max}}$ is shown: again, as expected, values greater than zero mean that the bound $\delta_{\text{max}}$ is never overcome. Please see text for more details.
The parameters of the bisimulation function $V(y_1, y_2, \{c_i\}_{i=0}^5)$ between $D_1$ and five versions of system $D_2$ with $w_2 \in \{-16, -17, -18, -19, -20\}$. Here the case in which the initial conditions of the observable variables are different ($y_1^0 \neq y_2^0$) and are in the closed and bounded interval $[-1, 1]$ is considered.

Table 5: $\delta_{\text{max}}$ obtained for the bisimulation function with parameters in Table 4. Again, increasing values of $\delta_{\text{max}}$ are found, as long as system $D_2$ behaves “more differently” with respect to $D_1$. The values of the upper bound given by $\delta_{\text{max}}$ are bigger than the ones in Table 3. This is again expected, insofar as we considered more general initial conditions for $y_1$ and $y_2$.

In Fig. 4, numerical simulations of the original system $\tilde{D}_1$ versus the different version of system $\tilde{D}_2$ are shown. Coherently, even with different initial conditions, the error on trajectories shown are completely consistent with the $\delta_{\text{max}}$ error in Table 5. Now, we consider the case of parameters $(I, w)$ (see Fig 2) in which there are three equilibrium points. In this case, by considering different initial conditions one may end up with systems that are more different with respect to the one in the global stable equilibrium point zone we have considered until now. We run the search for parameters of the bisimulation function in two illustrative cases: in the first one we set $I = -2.5$, $w_1 = 6$, $w_2 = 7$ and in the second $I = -5, w_1 = 10, w_2 = 11$. In the two examples the initial conditions are different, $y_1^0 \neq y_2^0$, and considered in the interval $[-1, 1]$. Table 6 shows the results for this bisimulation function search and the relative $\delta_{\text{max}}$. In this case $\delta_{\text{max}}$ measures the variability of the observable trajectories (in this case higher with respect to the previous example), and increases consistently with the greater numerical values of the distance between the stable equilibrium points. The numerical simulations shown in Fig. 5 are coherent with the $\delta_{\text{max}}$ bound found.

Finally, in the last session of tests, we explore the scalability of the proposed approach on systems of multiple neurons. We prepared two system comparisons
Figure 4: In Panel (a), numerical simulations of system \( \hat{D}_1 \) versus the different versions of system \( \hat{D}_2 \) were tested. \( \hat{D}_1 \) and \( \hat{D}_2 \) are one-neuron CTRNNs. In Panel (b), areas of \( \delta \)-solutions of \( \hat{D}_2 \) are shown (see Fig. 3). Note that in this example areas are larger in order to bound all the different initial conditions we subsumed in the computation. In Panel (c), values \((\delta_{\text{max}} - \delta_{\text{exp}})/\delta_{\text{max}}\) are plotted: as a result, the error on trajectories shown are completely contained, as it was expected, in the \( \delta_{\text{max}} \) error in Table 5.
Sample $D_1$ and $D_2$ trajectories in the 3-equilibria zone

Sample $D_1$ and $D_2$ trajectories in the 3-equilibria zone

Sample $D_1$ and $D_2$ trajectories with $y_1^0 \neq y_2^0$

Figure 5: In Panels (a) and (b), numerical simulations of system $\tilde{D}_1$ versus the different versions of system $\tilde{D}_2$ in the 3-equilibria zone are shown. In Panel (c), $(\delta_{\text{max}} - \delta_{\text{exp}})/\delta_{\text{max}}$ is shown: the errors on trajectories shown are completely contained, as it was expected, in the $\delta_{\text{max}}$ error in Table 6.
\[
I = -2.5, w_1 = 6, w_2 = 7
\]

\[
I = -5, w_1 = 10, w_2 = 11
\]

Table 6: Parameters for the bisimulation function and the relative \( \delta_{\text{max}} \) between systems \( D_1 \) and \( D_2 \). Two cases are presented: in the first we set \( I = -2.5 \), \( w_1 = 6 \), \( w_2 = 7 \) and in the second \( I = -5 \), \( w_1 = 10 \), \( w_2 = 11 \). In the two examples the initial conditions are different, \( y_1^0 \neq y_2^0 \), and considered in the interval \([-1, 1]\). In this case \( \delta_{\text{max}} \) measures the variability of the observable trajectories (in this case higher with respect to the previous example), and increases consistently with the greater numerical values of the distance between the stable equilibrium points.

- a comparison between networks with two neurons each \( D_1^{\text{two}} \) and \( D_2^{\text{two}} \)
- a comparison between networks with three neurons each \( D_1^{\text{three}} \) and \( D_2^{\text{three}} \)

In both cases the networks are fully-connected. On the second system we put a fixed input signal \( I \) that acts as a perturbation. For example, in the case of systems \( D_1^{\text{two}} \) and \( D_2^{\text{two}} \) we consider

\[
D_1^{\text{two}} = \begin{cases}
  y_1^1 &= -y_1^1 + w^{11} \cdot Pol_M(y_1^1) + w^{12} \cdot Pol_M(y_2^1) \\
  y_1^2 &= -y_1^2 + w^{11} \cdot Pol_M(y_1^1) + w^{22} \cdot Pol_M(y_2^1) \\
  h_1(y_1) &= y_1
\end{cases}
\]

and

\[
D_2^{\text{two}} = \begin{cases}
  y_2^1 &= -y_2^1 + w^{11} \cdot Pol_M(y_2^1) + w^{12} \cdot Pol_M(y_2^1) + I \\
  y_2^2 &= -y_2^2 + w^{11} \cdot Pol_M(y_2^1) + w^{22} \cdot Pol_M(y_2^1) + I \\
  h_2(y_2) &= y_2
\end{cases}
\]

To run the experiments we consider a quadratic form for the bisimulation function in all the variables, as we did previously. Furthermore to simplify the computation we set equal initial conditions for all the observation variables \( \{y_1, y_2\} \) and in the interval \([0, 1]\). To calculate each \( \delta_{\text{max}} \), we randomly choose a set of weights in \([0, 1]\) and perturb the second system with a fixed input \( I \in \{0, 1, 10\} \). We repeat this computation for 30 times and compute the mean value for \( \delta_{\text{max}} \) and its standard deviation. From the results in Table 7 and in Fig. 6, it is possible to appreciate the coherence of the measure with respect to the perturbation of the input signals and the increase in the number of neurons.

4 Conclusions

We have presented the dynamic network similarity (DyNeS) Algorithm, i.e., a procedure enabling one to compare the behaviour of neural networks, by introducing for the first time the bisimulation method to the non-linear dynamic network...
Figure 6: In Panels (a) and (b), the ratio \((\delta_{\text{max}} - \delta_{\text{exp}})/\delta_{\text{max}}\) is shown for system \(D_1^{\text{two}}\) versus system \(D_2^{\text{two}}\) and for system \(D_1^{\text{three}}\) versus system \(D_2^{\text{three}}\), respectively, with different inputs \(I \in \{0.1, 1, 10\}\). Again, as expected, values greater than zero mean that the bound \(\delta_{\text{max}}\) is never overcome.
Table 7: Mean value for $\delta_{\text{max}}$ and standard deviation computed on set of random weights for bisimulation between $D_{1\text{two}}$ vs $D_{2\text{two}}$ and $D_{1\text{three}}$ vs $D_{2\text{three}}$. The systems to be compared are identical except for a perturbation with a fixed input signal $I \in \{0.1,1,10\}$.

4.1 Discussion and Future Works

Although these preliminary results suggest that the application of the DyNeS Algorithm might be a viable effective approach for comparing dynamic networks, several issues raise in different directions, underlying the need of achieving further progress on them. Firstly, the more the polynomial approximation is improved leading to indistinguishable behaviour between approximate and “original” networks, the more complex the needed polynomial is, and the computational cost raises, especially when dealing with the argument of the sigmoidal function spread-
ing in large intervals. However, one can also directly use “polynomialized” versions of CTRNNs as models of neural circuits per se, as well as other dynamic neural models have been used in a “polynomialized” version (see e.g. Wilson, 1999).

Another research line concerns finding a subclass of dynamic networks for which an effective $\epsilon$ error of the polynomial approximation can be combined with the $\delta$ of the bisimulation, thus constructing a unique theoretical upper bound for the entire procedure. Furthermore, in case the search for the bisimulation fails, we cannot establish a measure of similarity, but at the same time we cannot assert that a bisimulation does not exist, because of 1) the arbitrariness of the construction of the Lyapunov-like bisimulation function and 2) the fact that we are trying to satisfy the sum of square conditions in Theorem 6, which implies the positive condition of Theorem 5, while the converse is not true. Thus, a critical aspect of the DyNeS Algorithm is related to the search of the appropriate bisimulation function, together with the computation of the coefficients of the polynomial. In order to simplify the search and construction of the proper Lyapunov-like function, effective matrix measure approaches could be imported from the field of synchronisation of chaotic neural networks (He and Cao, 2009; Cao and Wan, 2014; Chandrasekar et al., 2014). Interestingly, the network similarity problem specified in Section 2 can be expressed in a very general way for different models of static and dynamic neural networks. In particular, the presented DyNeS Algorithm is designed to work with CTRNNs but in principle could also be extended in order to encompass more general dynamic neural networks, thus establishing a similarity measure able to compare dynamic behaviours of different type of dynamic neural networks models. Finally, we put further emphasis on how this kind of approach paves the way to interesting possibilities for neuroscientists: for example, the introduction of formal logics “talking about” trajectories (see e.g. Fainekos et al., 2007) could enable one to ask more complex questions about dynamic network behaviours. Thus, also for those aspects, although in all the experiments described in this paper the similarity could be successfully accomplished by the computation of the coefficients of the proper bisimulation function, there are several issues for which additional theoretical and experimental investigations are needed.

Acknowledgments

The present research is funded by the Human Frontier Science Program (HFSP), award number RGY0088/2014, by the EU’s FP7 under grant agreement no FP7-ICT-270108 (Goal-Leaders), and by the ESF GAMES project, short visit grant n. 3014. The GEFORCE Titan used for this research was donated by the NVIDIA Corporation. The authors would also like to thank Patricia Bouyer, Giuseppe Trautteur, Guglielmo Tamburrini and Giovanni Pezzulo for the inspiring discussions, and the anonymous reviewers for their valuable comments and suggestions that greatly contributed to improving the final version of the paper.
